STATE OF WISCONSIN

CORRESPONDENCE/MEMORANDUM

Date: January 31, 2017

To: File

- *From:* Patrick J. Gavinski, P.E. SW Region Soils Engineer
- Subject: Soils Report Project I.D. 5845-01-06 Stoughton - Madison STH 138 Intersection USH 51, Dane County

<u>General</u>

This project is located on USH 51 in Dane County, at the STH 138 and Hoel Ave/Silverado Dr. Intersections in the City of Stoughton. The proposed improvement will reconfigure the intersections as roundabouts to handle the increased traffic.

<u>Geology</u>

This project is located in southern Dane County an area that was affected by the Green Bay lobe of the Late Wisconsin Stage glaciation. This particular project area is in an area of ground moraine.

<u>Soils</u>

The soils on project 5845-01-06 were mapped using NRCS's Web Soil Survey. The following table lists the soil series with general information. Note that in general the suitability of the material for use in highway construction decreases as the DGI number increases. For example, DGI 6 soils are typically better for highway construction than DGI 12 soils, though it is possible to use DGI 12 material.

Series Name	Description	Design Group Index (DGI)	Frost Index	Modulus of Subgrade Reaction (K)	AASHTO Classification	Approximate % of Project
Batavia	Silty clay on calcareous sandy loam	12,10	F-3	150,200	A-6	41
Dresden	Loam on calcareous sand and gravel	12	F-3	150	A-2, A-6	11
Gravel Pit	Gravel pit	-	-	-		5
Kidder	Loamy soil over calcareous sandy till	10,2	F-3, F-2	-	A-1, A-2, A-4, A-6	15
Kegonsa	Silt over calcareous sand and gravel	12	F-3	150	A-4, A-6	5
McHenry	Clay over sand with fines	10,2	F-3, F-2	200,300	A-4, A-6, A-7	5

Plano	Silty clay on calcareous sandy loam	12, 10	F-3	150, 200	A-4, A-6, A-7	10
Radford	Silty alluvium over paleosols	20,16	F-4	75,100	A-4, A-7	8

As part of this investigation, 13 roadway borings were taken over various times and locations. Copies of the soil borings may be found in Attachment A. The proposed plan and profile at the time of borings can be found in Attachment B. Copies of the NRCS soil maps and Soil Properties may be found in Attachment C.

Pavement Design Parameters

Based on NRCS information and our subsurface investigation, the following design values are recommended **WITHOUT Subgrade Improvement**.

Soil Support Value	4.2
Design Group Index	12
K Modulus	150 PCI
Frost Index	F-3
AASHTO Classification	A-7-6
Depth to Water	>5'
Depth to Rock	>8'

Using select material will help bridge the marginal subgrade soils and allow local traffic and construction loads to operate on the roadway even in periods of wet weather. Select material can increase pavement life by decreasing the amount of frost susceptible soil in the frost zone. In Addition, pipe under drain and french drains reduce frost heave by keeping moisture away from frost susceptible soils.

The following parameters should be used during the pavement design WITH Subgrade Improvement:

Soil Support Value	4.7
Design Group Index	12
K Modulus	375 PCI
Frost Index	F-3
AASHTO Classification	A-7-6(Deer Creek)
Depth to Water	>5'
Depth to Rock	>8'

Materials Availability

All common roadbuilding materials should be readily available in the area.

Compaction

Standard compaction is recommended for this project.

Erosion Control

Slopes and channels should be protected as per Chapter 10 of the FDM (See Procedure 10-5-35, Attachments 35.1 & 35.2). As always, embankment side slopes and cut slopes should be topsoiled, seeded, and mulched as early as possible to reduce the potential for erosion.

Fertilizer Type

For areas requiring topsoil, seeding, and mulch, Type B fertilizer is recommended.

Subgrade Improvement

Soils in this area are generally silts and silt loam. 16 inches of Select Crush Material is recommended for this project.

Discussion and Recommendations

Soil borings encountered existing 6" concrete pavement 2'–6' below existing grade in the areas of station 22+00NB and 25+00SB 30'RT(existing southbound Lanes). Refer to the elevations on the borings for depth to existing pavement. This existing pavement should be called out in the plan and removed if it will be encountered during construction. Boring 8 showed wet soil at the depth of the existing pavement, if the existing pavement will be encountered in this area ensure that adequate drainage of the select material is provided either by French drain or underdrain.

Typical topsoil thickness was 6".

An expansion factor of 1.33 should be used in earthwork calculations.

EBS should be estimated at 5% of the surface area of the project to a depth 1' below subgrade.

Clays and silts can be difficult to work with, especially when wet. The subgrade should be bladed and rolled daily to promote drainage.

Proper construction practices such as removing unsuitable materials underlying proposed embankments and benching into existing steep slopes as described in Section 205.3 of the 2017 State of Wisconsin Department of Transportation Standard Specifications for Highway and Structure Construction should be followed at all times. Cut and fill slopes should be held to a maximum of 2-1/2:1 whenever possible.

If sidewalks are replaced or new sidewalk added a 4-inch layer of base course under the new sidewalk is recommended.

If you have any question, please contact Pat Gavinski at (608) 516 – 6469.

Chemical Soil Properties

This table shows estimates of some chemical characteristics and features that affect soil behavior. These estimates are given for the layers of each soil in the survey area. The estimates are based on field observations and on test data for these and similar soils.

Depth to the upper and lower boundaries of each layer is indicated.

Cation-exchange capacity is the total amount of extractable cations that can be held by the soil, expressed in terms of milliequivalents per 100 grams of soil at neutrality (pH 7.0) or at some other stated pH value. Soils having a low cation-exchange capacity hold fewer cations and may require more frequent applications of fertilizer than soils having a high cation-exchange capacity. The ability to retain cations reduces the hazard of ground-water pollution.

Effective cation-exchange capacity refers to the sum of extractable cations plus aluminum expressed in terms of milliequivalents per 100 grams of soil. It is determined for soils that have pH of less than 5.5.

Soil reaction is a measure of acidity or alkalinity. It is important in selecting crops and other plants, in evaluating soil amendments for fertility and stabilization, and in determining the risk of corrosion.

Calcium carbonate equivalent is the percent of carbonates, by weight, in the fraction of the soil less than 2 millimeters in size. The availability of plant nutrients is influenced by the amount of carbonates in the soil.

Gypsum is expressed as a percent, by weight, of hydrated calcium sulfates in the fraction of the soil less than 20 millimeters in size. Gypsum is partially soluble in water. Soils that have a high content of gypsum may collapse if the gypsum is removed by percolating water.

Salinity is a measure of soluble salts in the soil at saturation. It is expressed as the electrical conductivity of the saturation extract, in millimhos per centimeter at 25 degrees C. Estimates are based on field and laboratory measurements at representative sites of nonirrigated soils. The salinity of irrigated soils is affected by the quality of the irrigation water and by the frequency of water application. Hence, the salinity of soils in individual fields can differ greatly from the value given in the table. Salinity affects the suitability of a soil for crop production, the stability of soil if used as construction material, and the potential of the soil to corrode metal and concrete.

Sodium adsorption ratio (SAR) is a measure of the amount of sodium (Na) relative to calcium (Ca) and magnesium (Mg) in the water extract from saturated soil paste. It is the ratio of the Na concentration divided by the square root of one-half of the Ca + Mg concentration. Soils that have SAR values of 13 or more may be characterized by an increased dispersion of organic matter and clay particles, reduced saturated hydraulic conductivity and aeration, and a general degradation of soil structure.

Data Source Information

Soil Survey Area: Dane County, Wisconsin Survey Area Data: Version 15, Sep 27, 2016

Engineering Properties

This table gives the engineering classifications and the range of engineering properties for the layers of each soil in the survey area.

Hydrologic soil group is a group of soils having similar runoff potential under similar storm and cover conditions. The criteria for determining Hydrologic soil group is found in the National Engineering Handbook, Chapter 7 issued May 2007(http:// directives.sc.egov.usda.gov/OpenNonWebContent.aspx?content=17757.wba). Listing HSGs by soil map unit component and not by soil series is a new concept for the engineers. Past engineering references contained lists of HSGs by soil series. Soil series are continually being defined and redefined, and the list of soil series names changes so frequently as to make the task of maintaining a single national list virtually impossible. Therefore, the criteria is now used to calculate the HSG using the component soil properties and no such national series lists will be maintained. All such references are obsolete and their use should be discontinued. Soil properties that influence runoff potential are those that influence the minimum rate of infiltration for a bare soil after prolonged wetting and when not frozen. These properties are depth to a seasonal high water table, saturated hydraulic conductivity after prolonged wetting, and depth to a layer with a very slow water transmission rate. Changes in soil properties caused by land management or climate changes also cause the hydrologic soil group to change. The influence of ground cover is treated independently. There are four hydrologic soil groups, A, B, C, and D, and three dual groups, A/D, B/D, and C/D. In the dual groups, the first letter is for drained areas and the second letter is for undrained areas.

The four hydrologic soil groups are described in the following paragraphs:

Group A. Soils having a high infiltration rate (low runoff potential) when thoroughly wet. These consist mainly of deep, well drained to excessively drained sands or gravelly sands. These soils have a high rate of water transmission.

Group B. Soils having a moderate infiltration rate when thoroughly wet. These consist chiefly of moderately deep or deep, moderately well drained or well drained soils that have moderately fine texture to moderately coarse texture. These soils have a moderate rate of water transmission.

Group C. Soils having a slow infiltration rate when thoroughly wet. These consist chiefly of soils having a layer that impedes the downward movement of water or soils of moderately fine texture or fine texture. These soils have a slow rate of water transmission.

Group D. Soils having a very slow infiltration rate (high runoff potential) when thoroughly wet. These consist chiefly of clays that have a high shrink-swell potential, soils that have a high water table, soils that have a claypan or clay layer at or near the surface, and soils that are shallow over nearly impervious material. These soils have a very slow rate of water transmission.

Depth to the upper and lower boundaries of each layer is indicated.

Texture is given in the standard terms used by the U.S. Department of Agriculture. These terms are defined according to percentages of sand, silt, and clay in the fraction of the soil that is less than 2 millimeters in diameter. "Loam," for example, is soil that is 7 to 27 percent clay, 28 to 50 percent silt, and less than 52 percent sand. If the content of particles coarser than sand is 15 percent or more, an appropriate modifier is added, for example, "gravelly."

Classification of the soils is determined according to the Unified soil classification system (ASTM, 2005) and the system adopted by the American Association of State Highway and Transportation Officials (AASHTO, 2004).

The Unified system classifies soils according to properties that affect their use as construction material. Soils are classified according to particle-size distribution of the fraction less than 3 inches in diameter and according to plasticity index, liquid limit, and organic matter content. Sandy and gravelly soils are identified as GW, GP, GM, GC, SW, SP, SM, and SC; silty and clayey soils as ML, CL, OL, MH, CH, and OH; and highly organic soils as PT. Soils exhibiting engineering properties of two groups can have a dual classification, for example, CL-ML.

The AASHTO system classifies soils according to those properties that affect roadway construction and maintenance. In this system, the fraction of a mineral soil that is less than 3 inches in diameter is classified in one of seven groups from A-1 through A-7 on the basis of particle-size distribution, liquid limit, and plasticity index. Soils in group A-1 are coarse grained and low in content of fines (silt and clay). At the other extreme, soils in group A-7 are fine grained. Highly organic soils are classified in group A-8 on the basis of visual inspection.

If laboratory data are available, the A-1, A-2, and A-7 groups are further classified as A-1-a, A-1-b, A-2-4, A-2-5, A-2-6, A-2-7, A-7-5, or A-7-6. As an additional refinement, the suitability of a soil as subgrade material can be indicated by a group index number. Group index numbers range from 0 for the best subgrade material to 20 or higher for the poorest.

Percentage of rock fragments larger than 10 inches in diameter and 3 to 10 inches in diameter are indicated as a percentage of the total soil on a dry-weight basis. The percentages are estimates determined mainly by converting volume percentage in the field to weight percentage. Three values are provided to identify the expected Low (L), Representative Value (R), and High (H).

Percentage (of soil particles) passing designated sieves is the percentage of the soil fraction less than 3 inches in diameter based on an ovendry weight. The sieves, numbers 4, 10, 40, and 200 (USA Standard Series), have openings of 4.76, 2.00, 0.420, and 0.074 millimeters, respectively. Estimates are based on laboratory tests of soils sampled in the survey area and in nearby areas and on estimates made in the field. Three values are provided to identify the expected Low (L), Representative Value (R), and High (H).

Liquid limit and *plasticity index* (Atterberg limits) indicate the plasticity characteristics of a soil. The estimates are based on test data from the survey area or from nearby areas and on field examination. Three values are provided to identify the expected Low (L), Representative Value (R), and High (H).

Report—Engineering Properties

Absence of an entry indicates that the data were not estimated. The asterisk '*' denotes the representative texture; other possible textures follow the dash. The criteria for determining the hydrologic soil group for individual soil components is found in the National Engineering Handbook, Chapter 7 issued May 2007(http://directives.sc.egov.usda.gov/ OpenNonWebContent.aspx?content=17757.wba). Three values are provided to identify the expected Low (L), Representative Value (R), and High (H).

Water Features (WI)

This table gives estimates of various soil water features. The estimates are used in land use planning that involves engineering considerations.

Hydrologic soil groups are based on estimates of runoff potential. Soils are assigned to one of four groups according to the rate of water infiltration when the soils are not protected by vegetation, are thoroughly wet, and receive precipitation from long-duration storms.

The four hydrologic soil groups are:

Group A. Soils having a high infiltration rate (low runoff potential) when thoroughly wet. These consist mainly of deep, well drained to excessively drained sands or gravelly sands. These soils have a high rate of water transmission.

Group B. Soils having a moderate infiltration rate when thoroughly wet. These consist chiefly of moderately deep or deep, moderately well drained or well drained soils that have moderately fine texture to moderately coarse texture. These soils have a moderate rate of water transmission.

Group C. Soils having a slow infiltration rate when thoroughly wet. These consist chiefly of soils having a layer that impedes the downward movement of water or soils of moderately fine texture or fine texture. These soils have a slow rate of water transmission.

Group D. Soils having a very slow infiltration rate (high runoff potential) when thoroughly wet. These consist chiefly of clays that have a high shrink-swell potential, soils that have a high water table, soils that have a claypan or clay layer at or near the surface, and soils that are shallow over nearly impervious material. These soils have a very slow rate of water transmission.

If a soil is assigned to a dual hydrologic group (A/D, B/D, or C/D), the first letter is for drained areas and the second is for undrained areas.

Surface runoff refers to the loss of water from an area by flow over the land surface. Surface runoff classes are based on slope, climate, and vegetative cover. The concept indicates relative runoff for very specific conditions. It is assumed that the surface of the soil is bare and that the retention of surface water resulting from irregularities in the ground surface is minimal. The classes are negligible, very low, low, medium, high, and very high.

The *months* in the table indicate the portion of the year in which a water table, ponding, and/or flooding is most likely to be a concern.

Water table refers to a saturated zone in the soil. The water features table indicates, by month, depth to the top (*upper limit*) and base (*lower limit*) of the saturated zone in most years. Estimates of the upper and lower limits are based mainly on observations of the water table at selected sites and on evidence of a saturated zone, namely grayish colors or mottles (redoximorphic features) in the soil. A saturated zone that lasts for less than a month is not considered a water table. (*Kind*) The kind of water table if a seasonal high water table exists in the soil. Entries are either apparent or perched. A perched water table is where free water is restricted from moving downward in the soil by a restrictive feature, in most cases a hard pan. Therefore, there is a dry layer of soil underneath a wet layer. An apparent water table is one where there is free water present in all horizons from its upper boundary to below 2 meters or to the depth of observation. The water table kind listed is for the first major component in the map unit.

Ponding is standing water in a closed depression. Unless a drainage system is installed, the water is removed only by percolation, transpiration, or evaporation. The table indicates *surface water depth* and the *duration* and *frequency* of ponding. Duration is expressed as *very brief* if less than 2 days, *brief* if 2 to 7 days, *long* if 7 to 30 days, and *very long* if more than 30 days. Frequency is expressed as none, rare, occasional, and frequent. *None* means that ponding is not probable; *rare* that it is unlikely but possible under unusual weather conditions (the chance of ponding is nearly 0 percent to 5 percent in any year); *occasional* that it occurs, on the average, once or less in 2 years (the chance of ponding is 5 to 50 percent in any year); and *frequent* that it occurs, on the average, more than once in 2 years (the chance of ponding is more than 50 percent in any year).

Flooding is the temporary inundation of an area caused by overflowing streams, by runoff from adjacent slopes, or by tides. Water standing for short periods after rainfall or snowmelt is not considered flooding, and water standing in swamps and marshes is considered ponding rather than flooding.

Duration and *frequency* are estimated. Duration is expressed as *extremely brief* if 0.1 hour to 4 hours, *very brief* if 4 hours to 2 days, *brief* if 2 to 7 days, *long* if 7 to 30 days, and *very long* if more than 30 days. Frequency is expressed as none, very rare, rare, occasional, frequent, and very frequent. *None* means that flooding is not probable; *very rare* that it is very unlikely but possible under extremely unusual weather conditions (the chance of flooding is less than 1 percent in any year); *rare* that it is unlikely but possible under unusual weather conditions (the chance of flooding is 1 to 5 percent in any year); *occasional* that it occurs infrequently under normal weather conditions (the chance of flooding is 5 to 50 percent in any year); *frequent* that it is likely to occur often under normal weather conditions (the chance of flooding is more than 50 percent in any year but is less than 50 percent in all months in any year); and *very frequent* that it is likely to occur very often under normal weather conditions (the chance of flooding is more than 50 percent in all months of any year).

The information is based on evidence in the soil profile, namely thin strata of gravel, sand, silt, or clay deposited by floodwater; irregular decrease in organic matter content with increasing depth; and little or no horizon development.

Also considered are local information about the extent and levels of flooding and the relation of each soil on the landscape to historic floods. Information on the extent of flooding based on soil data is less specific than that provided by detailed engineering surveys that delineate flood-prone areas at specific flood frequency levels.
